What is buspirone?

Buspirone is a medication that has been used to treat anxiety. The brand name for buspirone is Buspar®.

Sometimes when people find out they are pregnant, they think about changing how they take their medication, or stopping their medication altogether. However, it is important to talk with your healthcare providers before making any changes to how you take your medication. Your healthcare providers can talk with you about the benefits of treating your condition and the risks of untreated illness during pregnancy. For more information on anxiety, see our fact sheet here: https://mothertobaby.org/fact-sheets/anxiety-fact/.

Some people may have a return of their symptoms (relapse) if they stop this medication. If you plan to stop this medication, your healthcare provider may suggest that you slowly lower the dose instead of stopping all at once. Stopping this medication suddenly can cause some people to have withdrawal symptoms. It is not known what effect, if any, withdrawal could have on a pregnancy.

I take buspirone. Can it make it harder for me to get pregnant?

It is not known if buspirone can make it harder to get pregnant.

Does taking buspirone increase the chance of miscarriage?

Miscarriage is common and can occur in any pregnancy for many different reasons. Studies have not been done to see if buspirone can increase the chance of miscarriage.

Does taking buspirone increase the chance of birth defects?

Every pregnancy starts out with a 3-5% chance of having a birth defect. This is called the background risk. It is not known if buspirone can increase the chance of birth defects above the background risk. Information from a pregnancy registry found no birth defects among 72 infants exposed to buspirone during pregnancy.

Does taking buspirone in pregnancy increase the chance of other pregnancy-related problems?

Studies have not been done to see if buspirone can increase the chance of other pregnancy-related problems, such as preterm delivery (birth before week 37) or low birth weight (weighing less than 5 pounds, 8 ounces [2500 grams] at birth).

I need to take buspirone throughout my entire pregnancy. Will it cause withdrawal symptoms in my baby after birth?

The use of some medications during pregnancy can cause temporary symptoms in newborns soon after birth. These symptoms are sometimes referred to as withdrawal. There is a report of one infant with decreased growth, tremors, low muscle tone, low blood sugar, and trouble feeding. The infant was exposed to buspirone, other medications, and cigarette smoke during pregnancy. It is not known if the symptoms in the baby were due to buspirone, other exposures, or a combination of factors. It is important that your healthcare providers know you are taking buspirone so your baby can be monitored if needed.

Does taking buspirone in pregnancy affect future behavior or learning for the child?

Studies have not been done to see if buspirone can increase the chance of behavior or learning issues for the child.

Breastfeeding while taking buspirone:

Information on the use of buspirone in breastfeeding is limited. One report included a person who took buspirone (15mg/ 3 times a day) while breastfeeding. The levels of the medication were checked once and were too low to be found in the breastmilk. There are reports that looked at effects of buspirone in breastfed infants. One report found no
short-term side effects in an 11-week-old baby whose mother was taking 2 medications including 10 mg/day of buspirone. Another report described seizure-like activity in a 3-week-old infant. However, the authors suggested that if one of the 3 prescription medications that the mother was taking contributed to the effects seen in the baby, it was unlikely to be buspirone. If you suspect the baby has any symptoms, contact the child’s healthcare provider. Be sure to talk to your healthcare provider about all your breastfeeding questions.

*If a male takes buspirone, could it affect fertility or increase the chance of birth defects?*

It is not known if buspirone could affect male fertility (ability to get partner pregnant) or increase the chance of birth defects above the background risk. Studies by the manufacturer reported decreased libido (less desire to have sex), delayed ejaculation, and impotence (inability to get and maintain an erection). These issues can affect male fertility. In general, exposures that fathers or sperm donors have are unlikely to increase risks to a pregnancy.
